Objective: Integrating ER/PR receptors into clinical risk stratification is still under investigation and is proving to be an important component in endometrial cancer management. This study aimed to investigate the prognostic value of ER/PR receptors specifically its correlation with lymph node metastasis in black women which form a vulnerable group associated with poor outcomes. Methods: We reviewed black females (n = 70) diagnosed with endometrial cancer at our institution from 2015–2018 including endometroid/non-endometroid histology, FIGO stage I–IVA, grade 1–3 for ER/PR receptors and presence or absence of pelvic lymph nodes based on pre-operative endometrial curettage and post-surgical pathology specimens. Results: Majority of our patients were postmenopausal (59 out of 70) 84%. FIGO stage 1 and 2 constituted 72% (50 out of 70). Endometroid histology constituted 39 out of 70 (55%) cases and non-endometroid histology which includes serous, clear cell and carcinosarcomas constituted 45% of the cases. Loss of estrogen receptor (ER-) was observed in 19 of 70 patients (27%) and loss of progesterone receptor (PR-) was observed in 22 patients (31%) which was significantly associated with lymph node metastasis (p < 0.05). Subgroup analyses showed a significant association between PR+ and absence of lymph node metastasis in cases of endometroid cancer (p < 0.05). Nevertheless, there was no statistically significant association between ER receptors and lymph node metastasis in patients with endometrioid cancer. In non-endometroid histology both ER- and PR- were found to be statistically significantly associated with lymph node involvement. Conclusion: Loss of ER and PR receptors independently predicts lymph node metastasis in endometrial cancers in black women.

1. Introduction
Endometrial cancer is the most common gynecological malignancy in the United States [1]. Endometrial cancers are further divided into endometroid and non-endometroid histology. Non-endometroid histology includes serous, carcinosarcomas which are associated with poorer prognosis. Risk factors for endometrial cancers mainly includes obesity, early menarche and late menopause, unopposed estrogen, and family history of endometrial cancer [2]. About 80% of the endometrial cancers are endometroid and are diagnosed early with better prognosis [3]. There is a subset of the population that fail to reach 5 year overall survival even with endometroid histology and early stage of the disease [4]. Various prognostic indicators including FIGO stage, grade and histology have been used for risk assessment and for treatment decisions. However, estrogen (ER) and progesterone (PR) receptor status are considered the most significant prognostic markers for endometrial cancer [5–7].

Racial disparity specially in the survival rates for endometrial cancer is evident and has been increasing over the last 10 years [8]. Black women have a 90% higher 5-year mortality than white females. Black women are diagnosed at an advanced stage and have a higher proportion of non-endometroid histology associated with poor prognosis [9]. To address the gaps between black and white women comprehensive studies are required to assist us in better treatment decisions to improve survival in black women. Our study aimed to investigate if the correlation between hormone receptor status and lymph node metastasis holds true in black females which could aid in treatment protocols.

Gene expression of ER and PR receptors have been directly associated with prognosis of endometrial cancer in terms of survival. Loss of ER- and PR- receptors independently predict lymph node metastasis and shorter disease-free survival (DFS) [10]. Pre-operative endometrial curettage or biopsy is the first step in diagnosis and to identify receptor (ER/PR) status. Identifying the receptor status specially in surgical operable stages can help to individualize surgical therapy in endometrial cancer. Routine lymph node dissection has not been confirmed to improve survival and is associated with increased complications [11]. Hence, receptor status could aid us in moving forward with aggressive treatment with pelvic lymphadenectomy specially in our population of
black females. Our aim is to help in creating an algorithm for management of endometrial cancer for our population.

Integrating biomarkers like ER/PR receptors with clinical and pathological parameters will improve risk stratification and will guide us in predicting the future course of treatment and possible long-term survival. Unlike some cancers like breast, where hormonal biomarkers have been incorporated for tailored therapy, targeted agents are still in its primitive stage in endometrial cancers [12].

Our study aimed at investigating (1) association of loss of ER and PR receptors with lymph node metastasis as detected in the post-operative specimens (2) role of ER and PR receptors in both endometroid and non-endometroid subtypes separately (3) to check if receptor hypothesis holds true for black females.

2. Methods and materials
2.1 Participants

We reviewed black females with endometrial cancer (n=70) at our institution diagnosed between 2015–2018. Patients included in our study underwent pre-operative endometrial curettage or biopsy followed by trans-abdominal or laparoscopic surgery with lymph node dissection/sampling or debulking surgery in advanced stage cancer. We included patients with FIGO stage I–IVA, grade 1–3, both endometroid and non-endometroid histology. Patients with distant metastasis were excluded from the study. Baseline characteristics including age, BMI, pre/post-menopausal status and were noted. Biomarkers specially ER and PR receptors status were noted for both endometroid/non-endometroid histology. Pelvic and para-aortic nodes involvement were identified from post-operative specimens.

2.2 Immunohistochemical staining and evaluation

ER, PR expression was assessed by IHC’s using formalin-based paraffin embedded samples. The expression of ER, PR were evaluated by at least 2 pathologists. Staining of ER/PR was considered positive if the nuclei were stained in >1% of the cells.

2.3 Statistical analysis

Statistical analyses were performed with Python3.7 (SciPy, NumPy, Pandas, and Matplotlib libraries) using Fisher’s Exact test exploring associations between categorical variables (ER/PR and Lymph nodes Metastasis). To corroborate the findings, estimated odds ratios (OR) for lymph node metastasis to ER/PR was calculated. The analysis was done for independent ER/PR positive and negative, for all subjects and for the two subtypes (endometroid and non-endometroid). All statistical tests were two-sided and considered significant if $p < 0.05$. Post-hoc power calculation was done using the software G*Power 3.1 (HHU, Düsseldorf, Germany).

Descriptive statistics were used to characterize baseline parameters like age, BMI including molecular targets for non-endometroid histology. Weighted percentages were used to summarize the data. Our study was approved by the institutional review board (IRB).

3. Results

3.1 General patient characteristics

We included all black females only (n=70) that were diagnosed with endometrial cancer from 2015–2018 and who underwent laparoscopic or transabdominal surgery or debulking surgery (Table 1).

Table 1. Characteristics of 70 endometrial cancer patients included in the study.

Volume 42, Number 4, 2021 803
patients with distant metastasis were excluded from the study.

Grade—Majority of our patients 32/70 (45%) had grade 3
disease followed by grade 1 in 32%.

Histology—Endometroid cancers formed 39/70 (55%) of
our sample followed by non-endometroid which includes
serous in 22% and carcinosarcoma in 16%.

3.2 Hormone receptors and lymph nodes

We observed presence of hormone receptors which in-
volved ER and PR receptors in pre-operative endometrial
specimens using biopsy or curettage samples. Presence or ab-
sence of lymph node involvement was detected in samples
obtained through laparoscopic or transabdominal or debulk-
ing surgery. Presence or absence of hormone receptors and
its correlation with lymph node metastasis was observed in
the entire sample and a subgroup analysis was done separately
for endometroid and non-endometroid histology. Estrogen
receptors were positive (ER+) in 51/70 (72%) of our sam-
ples and PR receptors were positive (PR+) were positive in
48/70 (68%). On subgroup analysis in endometroid cancers
35/39 (89%) were ER+ while 36/39(92%) were PR+. The
non-endometroid variant showed ER+ in 16/31 (51%) and
PR+ 12/31 (38%) of the samples (Fig. 1).

Loss of estrogen receptor (ER-) was observed in 19 of 70
patient samples (27%) and found to be significantly associated
with lymph node metastasis ($p < 0.05$). Progesterone recep-
tor loss was noted (PR-) in 22 (31%) and was associated with
metastasis of lymph node (Table 2). On sub-group analysis
the association between ER/PR with lymph node metastasis
in patients with endometroid and non-endometroid (com-
prising of serous, carcinosarcoma and clear cell) endometrial
cancer showed significant association between PR+ and ab-
sence of lymph node metastasis in endometroid cancer type.
There was no statistically significant association ($p = 0.10$)
between ER and lymph node metastasis in patients with en-
dometroid type cancer. In case of non-endometroid cancers
(comprising of serous, carcinosarcoma and clear cell) both
ER- and PR- were found to be associated with metastasis to
the lymph nodes ($p < 0.05$) (Table 3).

All our patients were closely followed up as an outpatient.
Patients eligible for adjuvant therapy post-surgery received
necessary chemo-radiation according to the guidelines. At
the end of one-year post-treatment 68/70 (97%) were alive.
Nearly 40% of patients had progression in the form of metas-
tasis to lung, vagina, or local spread. A noticeable obser-
vation made was majority of our patients with progression
at one-year follow-up post treatment were from the non-
endometroid group.

4. Discussion

We report for the first time the role of hormonal receptors and its significance with respect to lymph node metastasis in black women. Involvement of pelvic and para-aortic lymph nodes by itself is an indicator of poor outcomes in addition to race which is associated with poor survival. Our study aimed to observe if hormone receptor status and its association with lymph node metastasis holds true in black women which could help in creating proper algorithms for aggressive treatment in this vulnerable group [9]. This would also help us in identifying individuals who would benefit from pelvic lymph node dissection which has its own complications [11]. Black women have been seen to be diagnosed at a later stage and have higher proportion of non-endometrioid histology [13, 14].

Lymph node sampling is considered an important component in endometrial cancer management in particular for high grade and high-risk endometrial cancer [15]. Routine lymphadenectomy in every patient with endometrial cancer is not recommended, as it is associated with longer operative times and significant post-operative complications specially in obese women which form a significant proportion of black women diagnosed with endometrial cancer [16]. Our study reported a mean BMI of 36.94 kg/m² keeping these patients at a higher risk of complications if subjected to extensive pelvic and para-aortic lymph node dissection. Improved tools to identify prognostic indicators like hormone receptors status (ER/PR) can guide us in identifying patients who will benefit from lymph node dissection. Pre-operative curettage or biopsy samples for receptor status identification should form the first step in the algorithm for management of endometrial cancers. Studies have also shown that non-endometrioid subtypes which are higher in black women and associated with poor outcomes will benefit from these tools to a greater extent. Non-endometrioid cancers have been associated with deeper myometrial infiltration and have consistently demonstrated lymph node metastasis [17]. Larger and adequately powered randomized trials are required to study the effects of planned lymphadenectomy in black women who satisfy the pre-requisite based on hormone receptors which is beyond the scope of this study.

Various studies identifying the prognostic value of ER and PR receptors were evaluated across various histological subtypes [18, 19]. These studies have independently predicted prognostic value of ER and PR receptors in early stage and low-grade endometrial cancer. A study conducted by Trovik et al. [18] significantly predicted loss or ER (-) and PR (-) and its association with lymph node involvement thereby adding predictive and prognostic value specially in the low-risk group. This study also predicted poor disease-free survival (DFS) in patients with a negative receptor status. In our study, which is probably the first study to test this hypothesis in black women, who generally have a higher mortality rate and late stage of presentation in comparison to their white counterparts. We reported a statistically significant association of loss of ER (-) and PR (-) with positive lymph node involvement. On subgroup analysis with endometrioid and non-endometrioid subtypes we observed significant predictive value of both ER and PR receptors independently specially in serous and carcinosarcomas. This information can be utilized while addressing treatment strategies for black women with endometrial cancer. We strongly recommend conducting larger multicentric trials on black women for better understanding of the disease pattern and course of disease in black females. Creating a treatment algorithm that could be acceptable universally for this group could help in improving survival outcomes.
Studies have reported unfavorable subtypes like serous and carcinosarcomas in higher proportions in black women [20]. Our study revealed ER+ in 41% and PR+ in 33% with carcinosarcomas and 43% and 31% with serous variants respectively [21]. Incorporating molecular testing in the treatment algorithm specially in black women with non-endometroid subtype is our recommendation.

Biomarkers like ER/PR receptors have been incorporated in the treatment algorithm for breast cancers. Despite sufficient studies in endometrial cancers, these biomarkers are not routinely used to tailor endometrium cancer management. Our study can add to the database and form the basis of a multicentric prospective trial in black women. We recommend using these biomarkers in patient risk stratification in a metastatic setting.

We acknowledge the limitation of our study being the sample size of our population (n-70) which is smaller than other studies assessing the role of endometrial receptors and its correlation. However, our study is exclusively limited to black females and is among the few studies assessing the correlation in this vulnerable group. Our study is based on a single institutional database and we are working in acquiring data and involving multiple centers in our study in the future. We expect better statistical correlation with an increase in our sample size.

Our study was not designated to test the role of lymphadenectomy in endometrial cancer but to incorporate molecular and targeted staging in the treatment algorithm specially in black women. As reported in our data we recommend that hormone status should be incorporated in randomized trials for surgical and systemic treatment. Preoperative differentiation of patients can also decrease the burden of tertiary centers, as those with local and low-grade disease can be managed at a local center while advanced disease can be referred to specialized centers [22]. This stratification can only be possible if we have well established guidelines and algorithms.

5. Conclusions

Our results suggest that loss of ER and PR receptors independently predicts lymph node metastasis and has the potential of being used as a prognostic indicator in endometrial cancer in black females. However, further analysis and larger multicentric randomized trials are needed to ascertain their true prognostic significance. Molecular staging and targeted agents are the need of the hour in improving survival outcomes in endometrial cancers specially in black women.
